PROJECT OVERVIEW · PLAIN LANGUAGE

Harbour Twin

A 3D computer copy of a Harbour, built only from free public data, that tracks ships, finds the ones that are not announcing themselves, plans for floods, and checks its own accuracy.

Shivaji Patil · shivaji@shivajipatil.com · October 2026 · Vancouver and St. John's, Canada

77
ships found by satellite radar in one Vancouver pass, including ones broadcasting nothing on AIS

347
models rebuilt-free over 4 hours, 134 km downriver projection reports

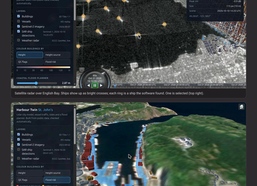

98.7%
of 1,249 building heights measured to lower, not guessed

70
automated checks that must pass before results are published

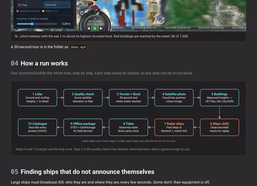

Orange objects are the maritime ones: satellite radar and ship positions. Everything is read directly from the organisations that publish it; nothing is copied by hand.

01 What it looks like

Vancouver Harbour from False Creek. Buildings are coloured by measured height; coloured dots and trails in Burrard Inlet are ships replaying their recorded movements, with the water level following the real rise on the scene clock.

Satellite radar, not English Bay. Ships show up as bright crosses; each ring is a ship the software found. One is selected (top right).

St. John's entrance with the sea 3 m above its tide gauge datum and flood. Red buildings are reached by the water 96 of 1,249.

A 3D-zoomed tour is in the folder as `demo.mp4`.

04 How a run works

One command builds the whole town, step by step. Each step saves its results, so any step can be re-run alone.

05 Finding ships that do not announce themselves

Large ships must broadcast AIS: who they are and where they are, every few seconds. Some don't: their equipment is off, broken, or deliberately switched off. Satellites radar, which can't be switched off, can see them in any weather, day or night, through cloud. Comparing the two is a core task in **maritime domain awareness**.

The comparison needs ship positions recorded at the instant the satellite passes (named 2023 and 14:21 UTC over Vancouver, each repeating every 12 days). The software predicts the next pass.

Every ship-detection dataset goes through this before it is used. The results are in `radarSentinelVancouver_REPORT.md`.

What the checks caught

- **A standard tool was wrong by up to a metre.** The common mapping library (PROJ) converts Canadian heights to the global reference with an error of 0.26 m in Vancouver and 1.05 m in St. John's. The pipeline does the conversion explicitly, and a test makes sure it can't be switched off.
- **Published building heights are often wrong.** A 190.8 m tower was listed as 10 m tall in OpenStreetMap. 777 such errors were found and fixed. Results are proven to be more rather than less reliable.
- **A ship was in the sky.** A ship in the harbour, found by noticing at the vertical edge of the radar image.
- **A second city tested for assumptions.** A missing datum definition, and a tide gauge in St. John's that does not publish the usual height reference. So tend is now converted another way, and cross-checked.

06 How we know the results are right

Honest status. The ship finding works on real radar images. The matching step is tested with made-up data so far, because the bundled ship recording does not overlap a satellite pass. Reconciling ships during the next pass (with planned AIS) should produce the first real comparison.

07 What is in the folder

08 Reproduce it yourself

Pick the path that matches what you want. Each one builds on the ones before it.

Before you start: download the whole `harbour-twin` folder (Google Drive gives you a zip, unzip it). Open a terminal in the unzipped folder. Linux and macOS work directly; on Windows, use WSL (Windows Subsystem for Linux).

A. Just look at it

Needs: Python 3 (any recent version) and an internet connection for the 3D library and base map.

```
python -m http.server 8765 --directory web
```

Open http://127.0.0.1:8765 in Chrome, Edge or Firefox. For St. John's open `http://127.0.0.1:8765/?accountName=...`. Stop it with `Ctrl+C`.

Expect: Downtown Vancouver in 3D, ships moving in the harbour, a panel on the left with layers, flood planner and data quality numbers. The 1,249 ship detections' 3D view that needs setup.

Opening `web/index.html` by double-clicking does not work: browsers block a page from reading its own data files unless it is served, which is what the first command does.

B. Run the checks

Needs: Python 3.10 or newer, Node.js 18 or newer, and `make`.

```
make                  # install the Python packages and the 3D-model validator (about 30 s)
make test             # the automated checks
make validate         # checks every 3D building tile against the official standard
```

Expect: 87 passed, 1 skipped, then `{"tiles": 96, "errors": 0, "warnings": 0}`. The 1 skipped check needs the large files. To include them, copy them in and run the checks again.

```
cp -r /products/data/* data/
make test
make serve            # same viewer as path A, using the installed Python
```

C. Rebuild everything from the original sources

Needs: Earth-engine account, Copernicus account, and the parts of each dataset it needs, not whole files.

```
make data             # downloads and checks the inputs
make data-validate    # the same checks, now on what you just built
make data-Vancouver   # or: data-<name> pipeline/<your_settings>.toml
make test
```

Expect: progress messages for each step ("Step lidar done in 12 s" and so on), then the same checks passing. Numbers can move slightly if a source publishes newer data.

D. Record your own ship, and compare them with radar

Needs: path B done and a free key from **aisstream.io** (sign in, copy the API key).

```
echo "AISSTREAM_API_KEY=paste-your-key-here" > .env
make record-ships     # when the radar satellite next passes over
make record-ship-list # start about an hour before that pass, records 2 hours
make all              # then re-check, fuse radar ships, matches, then
```

Expect: after the satellite image appears in the public catalogue (usually 1 to 3 days after the pass), `make all` reports how many radar ships were matched to AIS and how many are dark vessel candidates, and how many AIS ships the radar did not see. The viewer's Ships panel shows the same.

Recording adds to any earlier recording. To keep them apart, move the old one first: `mv data/cache/vancouver/ais_raw.jsonl data/cache/vancouver/ais_raw_old.jsonl`.

E. Serve it like a product (Docker)

Needs: the large files in `data/` (path C or a download with the Compose plugin).

```
docker compose up --build     # first run downloads the images (a few minutes)
```

Then open `http://localhost:8080/?accountName=...&tileset=...` (the exact URL is printed). Stop with `Ctrl+C`, or `docker compose down` in another terminal. Change the port by editing `HARBOUR_TWIN_PORT=8080` in the file `.env`.

If something goes wrong

What you see	What it means and what to do
`Could not resolve host`	A short network hiccup reaching one of the data providers. Run the same command again; every step can be re-run safely.
`0 skipped`	The large files are not in `data/`. Copy them from `products/` (path B) or rebuild them (path C).
Blank viewer page	The page was opened by double-clicking. Use the `python3 -m http.server` command from path A.
`make: command not found`	Install it: `sudo apt install make` on Ubuntu/Debian, `xcode-select --install` on macOS, or use WSL on Windows.
`npm: command not found`	Install Node.js 18+ from nodejs.org. It is only needed for `make validate`.
`Set AISSTREAM_API_KEY`	Only recording needs a key (path D). Everything else works without one.

09 Limits worth knowing

- The flood planner is a planning screen. It uses still water and the shape of the ground, not waves, wind or drainage.
- The radar matching has not yet been run on a real ship-recording make during a satellite pass (see section 5).
- How bright a spot must be to count as a ship was set by inspecting real images, not from a labelled training set.
- All runtime from volunteer resources, so coverage is uneven and many viewers never report their type.
- Buildings never that the laser-scan flat back to published heights, not measured ones.

10 Words used here

AIS

Automatic Identification System: radio messages in which ships report their identity, position, speed and course.

SAR (radar)

Synthetic Aperture Radar: a satellite sends microwaves and records the echo. Works at night and through cloud, metal ships echo brightly against a dark sea.

Sentinel-1 / -2

European Space Agency satellites. Sentinel-1 carries radar, Sentinel-2 takes colour images. Their data is free.

Lidar

Laser scanning from aircraft. Measures the ground and rooftops to within centimetres; the most accurate height data used here.

Dark vessel

A ship seen by sensors such as radar but not reporting over AIS. Here always a candidate, for a person to review.

CFAR

Constant False Alarm Rate: a standard radar method that calls a spot a target only if it is much brighter than its own surroundings.

Vertical datum

The "zero" that heights are measured from. Different datasets use different zeros, metres apart; mixing them is a common, silent error.

Digital twin

A working computer copy of a real place, built from measurements and kept checkable.

STAC

SpatioTemporal Asset Catalog: a standard way to describe and find map and satellite data, used here both to find inputs and describe outputs.

GTFS, GeoPackage

Standard map-file formats used on devices that work without internet, such as ships and drones.

City3DB

An open-format for 3D city models. Here the JSON form of CityGML, read by city-loading tools. The buildings are exported to it as simply-closed blocks.

OGC API - Features

A standard web interface for map data: any GIS can ask it for "buildings in this box" or "flagged buildings" and get them back.

Object storage

Cloud file storage such as Amazon S3. Publishing the products there lets anyone read them over the web without a special server.

OSI

The 3D format ArcGIS uses for scene layers. The buildings are also delivered as an OSI package, checked down to individual roof heights.

3D Tiles

An open standard for streaming 3D city models to a browser.
